Photoluminescent lanthanopolyoxotungstate core/shell nanoparticles are prepared by the encapsulation of lanthanide-containing polyoxometalates (POMs) with amorphous silica shells. The preparation of morphological well-defined core/shell nanoparticles is achieved by the hydrolysis of tetraethoxysilane in the presence of POMs using a reverse microemulsion method. The POMs used are decatungstolanthanatoates of [Ln(W_18O_{62})]^− type (Ln(III) = Eu, Gd and Tb). Photoluminescence studies show that there is efficient emission from the POM located inside the SiO_2 shells, through excitation paths that involve O → Eu/Tb and O → W ligand-to-metal charge transfer. It is also shown that the excitation of the POM containing europium(III) may be tuned towards longer wavelengths via an antenna effect, by coordination of an organic ligand such as 3-hydroxypicolinate. The POM/SiO_2 nanoparticles form stable suspensions in aqueous solution having the advantage of POM stabilization inside the core and the possibility of further surface grafting of chemical moieties via well known derivatization procedures for silica surfaces. These features together with the possibility of tuning the excitation wavelength by modifying the coordination sphere in the lanthanopolyoxometalate, make this strategy promising to develop a new class of optical bio-tags composed of silica nanobeads with multi-wavelength photoluminescent lanthanopolyoxometalate cores.

Introduction

Core/shell systems have been widely used in recent years, considering a series of advantages for specific applications,1,2 which include new clinical diagnosis platforms.3–5 The encapsulation of several types of nanoparticles with amorphous SiO_2 shells, using either the Stöber method6 or the microemulsion synthesis,7 has become a widespread technique.8,9 The high surface area-to-volume ratio, along with the relatively ease of surface functionalization of core/shell SiO_2 nanoparticles, allows their extensive use in the fabrication of biosensors,10–12 cell labelling13,14 and drug delivery systems.15,16 Lanthanopolyoxometalate-based materials have been investigated in particular due to their photoluminescent properties. Lanthanopolyoxometalates have been assembled in Langmuir–Blodgett films17,18 and in layer-by-layer deposition films,19,20 or incorporated in double layer hydroxides21 and in liquid crystals,22 envisaging new optically active materials. Polyoxometalates (POMs) have also been used in the fabrication of siliceous sol–gel hybrid materials.23 Green et al.24,25 reported the synthesis of Stöber type SiO_2 nanoparticles doped with Na_{13}[Eu(SiMoW_{10}O_{39})_{2}]_2 using a POM/poly-l-lysine conjugate. The POM/poly-l-lysine conjugate favoured the formation of hollow spherical nanocomposites, hence leading to an appealing system for optical monitoring of drug carriers. The latter work also reported SiO_2 nanospheres containing POMs evenly spread throughout the particle that were prepared by an alcosol route.

The preparation of POM-containing dense core/shell nanoparticles, not hollow and with a well-defined polyoxometalate core, is reported for the first time in the work presented here. Following our own studies of coupling lanthanide complexes, mainly of Eu(III) and Tb(III), to SiO_2 nanoparticles,26 we report here the preparation of core/shell POM/SiO_2 nanocomposites. Comparing to previous work with Ln(III) 3-hydroxypicolinate complexes,26 here the use of microemulsions as nanoreactors and Ln(III) polyoxometalate compounds allowed a better control of the morphological properties of the composite nanoparticles.

The POMs used here as starting materials were decatungstolanthanatoates of [Ln(W_18O_{62})]^− type (Ln(III) = Eu, Gd and Tb). The [Eu(W_5O_{18})]^− anion exhibits peculiar photoluminescence features, in particular, an abnormally high intensity of the ^5D_0 → ^7F_4 transition, which has been modelled by some of us in terms of the Ω_4 intensity parameters.27 An interesting and general feature of these POM/SiO_2 core/shell systems is the possibility to tune their optical properties by working on the coordination chemistry of the inner lanthanide complexes, varying the lanthanide centers or adding coordinated organic ligands. An organic–inorganic hybrid based on the europium(III) decatungstolanthanato and 3-hydroxypicolinic acid28 was also encapsulated in nanosilica. The 3-hydroxypicolinate ligand (picOH) acts as an antenna collecting photons and transferring energy to the lanthanide center, which leads to excitation wavelength tuning for photoluminescent nanosilicas containing...
these compounds. Mixed lanthanide nanocomposites with a 1 : 1 stoichiometry of either Eu : Tb or Eu : Gd were also prepared. The POMs, along with the POMs encapsulated in the nanosilica, were studied by photoluminescence. The effect of the organic ligand on the luminescence of the lanthanopolyoxotungstate inside the SiO₂ shell was also investigated.

### Experimental

#### Materials and chemicals

All reagents were purchased from Aldrich and used without further purification. The POMs Na₉[Gd(W₅O₁₈)₂]·14H₂O, Na₆[Gd(W₅O₁₈)₂]·20H₂O and Na₆[Tb(W₅O₁₈)₂]·14H₂O were prepared using the method described by Peacock and Weakley.²⁶

#### Instrumentation and characterization

Infrared spectra were obtained on a Mattson 7000 spectrophotometer using KBr pellets. FT-Raman spectra were recorded using a Bruker RFS100/S FT-Raman spectrometer (Nd:YAG laser, 1064 nm excitation). TEM images were obtained using a Hitachi H-9000 transmission electron microscope operating at an acceleration voltage of 300 kV. High-resolution TEM (HRTEM) and elemental mapping by X-ray energy dispersive spectroscopy (EDX) analysis were carried out with a JEOL 2200FS transmission electron microscope operating at an acceleration voltage of 200 kV.

The photoluminescence spectra were recorded between 12 K and room temperature on a Fluorolog-3 Model FL3 – 2T with double excitation spectrometer and a single emission spectrometer (TRIAX 320) coupled to a R928 photomultiplier, using a front face acquisition mode. The excitation source was a 450 W Xenon lamp. Emission was corrected for the spectral response of the monochromators and the detector using typical correction spectrum provided by the manufacturer and the excitation spectra were corrected for the spectral distribution of the lamp intensity using a photodiode reference detector. The lifetime measurements were acquired at room temperature with the setup described for the luminescence spectra using a pulsed Xe–Hg lamp (6 μs pulse at half width and 20–30 μs tail). The absolute emission quantum yields were measured at room temperature using a quantum yield measurement system C9920-02 from Hamamatsu with a 150 W Xenon lamp coupled to a monochromator for wavelength discrimination, an integrating sphere as sample chamber and a multi channel analyzer for signal detection. Three measurements were made for each sample so that the average value is reported. The method is accurate to within 10%.

#### Preparation of POM/SiO₂ nanocomposites

The nanocomposites were prepared by a reverse microemulsion method (W/O, water in oil microemulsions) for the hydrolysis of tetraethoxysilane (TEOS).‡ A W/O microemulsion containing Triton X-100 (3.68 mmol), 1-octanol (14.4 mmol), cyclohexane (86.1 mmol), TEOS (200 μL) and a POM (0.016 mmol) aqueous solution (1 mL H₂O) was mixed with a W/O microemulsion containing Triton X-100 (3.68 mmol), 1-octanol (14.4 mmol), cyclohexane (86.1 mmol) and ammonia (200 μL). The mixture was stirred for 24 h at room temperature, after which acetone was added in order to precipitate the nanoparticles. The white solid obtained was centrifuged, washed with ethanol and water, and dried in a desiccator under vacuum. The POMs used in the preparation of the nanocomposites (see Table 1 for numbering) were respectively: Na₉[Eu(W₅O₁₈)₂]·14H₂O for 1, Na₆[Tb(W₅O₁₈)₂]·14H₂O for 2, Na₆[Gd(W₅O₁₈)₂]·20H₂O for 3, a 1 : 1 mixture of the latter Eu and Tb POMs in aqueous solution for 4, a 1 : 1 mixture of the latter Eu and Gd POMs in aqueous solution for 5, the hybrid organic-inorganic compound Na₁₃[Eu(W₅O₁₈)₂(picOH)₄]·15H₂O for 6.

#### Preparation of Na₁₃[Eu(W₅O₁₈)₂(picOH)₄]·15H₂O

The compound was prepared following our previous method.²⁸ An aqueous solution of 3-hydroxypicolinic acid (3.04 mmol, in 30 mL of water) was added to an aqueous solution of sodium tungstate dihydrate (15.2 mmol, in 7 mL of water). The mixture was heated to 90 °C with stirring and a hot aqueous solution of europium(III) nitrate (1.52 mmol, in 2 mL of water) was slowly added. The resulting mixture was stirred and kept at 90 °C for 30 min. The mixture was allowed to cool at room temperature and the solid obtained was filtered, washed with ethanol and dried in a desiccator over silica gel.

#### Results and discussion

Core/shell POM/SiO₂ nanoparticles were obtained by the hydrolysis of tetraethoxysilane (TEOS) in the presence of POMs through a reverse microemulsion method. The POMs used as starting materials were the sodium salts of lanthanopolyoxotungstates [Ln(W₅O₁₈)₂]²⁺ with Ln(III) = Eu, Gd and Tb. A POM derived from [Eu(W₅O₁₈)₂]²⁺ and 3-hydroxypicolinic acid was also synthesized (Na₁₃[Eu(W₅O₁₈)₂(picOH)₄]·15H₂O) and was studied by photoluminescence. The effect of the organic stoichiometry of either Eu : Tb or Eu : Gd were also prepared.

encapsulated within SiO$_2$ shells. Table 1 lists the nanocomposites obtained in this work that are designated by POM/SiO$_2$ (the POM refers to the starting polyoxometalate anion). Also shown are the FT-IR and FT-Raman diagnostic bands for the POMs, as pure powders and in the respective SiO$_2$ nanocomposites.

The presence of polyoxotungstates in the POM/SiO$_2$ nanocomposites is clearly shown by several bands in the 700–1000 cm$^{-1}$ range in the infrared and Raman spectra (Table 1, and Fig. S1 and S2 in the ESI†), on top of SiO$_2$ vibrations. These bands are assigned to the POM terminal W=O stretches (933–948 cm$^{-1}$) and W–O–W stretching modes in edge-shared WO$_6$ octahedra (701–894 cm$^{-1}$). Raman spectra allow a better observation of the POM vibrational modes that are strongly hidden in the infrared spectra by the very intense bands due to amorphous silica. As will be discussed later, for each POM and derived nanocomposite, the lanthanide ion was also identified by photoluminescence.

The TEM images of the POM/SiO$_2$ composites show morphological uniform nanosized spheres, composed of a core of POM which is coated with amorphous SiO$_2$ (Fig. 1, 2a and 3). In [Eu(W$_5$O$_{18}$)$_2$]/SiO$_2$ (1) (Fig. 1a and 1b) the nanospheres are typically 35 nm in diameter containing a POM core that is 18 nm wide. In nanocomposites [Eu(W$_5$O$_{18}$)$_2$(picOH)$_4$]/SiO$_2$ (6) (Fig. 1c) the POM core is smaller, that is certainly due to a smaller ratio of POM:TEOS used in the synthesis of 6 due to the lower solubility of the starting POM-picOH hybrid. All the TEM images showed clear predominance of core/shell type particles with the POM assigned to the inner dark spots observed in the TEM images. EDX mapping confirmed the presence of tungsten from POMs mostly in the core and the presence of silica in all particle area (Fig. 2). The lanthanide ions were also detected by EDX and the corresponding peaks were located mainly in the particles cores (Fig. S3 and S4 in the ESI†).

As compared to our previous systems, the rather uniform morphological characteristics of the nanocomposites reported here can be related to the type of surfactant used and the ionic nature of the lanthanide-containing species. We suggest that the non-ionic surfactant (Triton X-100) molecules favour the formation of SiO$_2$ domains at the hydrophilic polyethylene oxide groups. As a consequence of condensation of the silica oligomers, resulting from TEOS hydrolysis at the W/O interface, the SiO$_2$ domains grow from the inner surfaces of the nanoreactors towards the centre thus encapsulating the POM species that remained in the water pools and became trapped in their interior (Scheme 1). The POM species remain predominantly in the

particles’ core, thus suggesting that during the formation of the silica matrix the dispersion of the POM in the silica network occurs to a lesser extent. The latter case would lead presumably to particles with a uniform contrast in the TEM images or with the material spread evenly throughout the particle. Furthermore, there was no evidence for the presence of more than one type of inorganic nanoparticles, for example composed of only SiO2 or chemically analogous composites, but with a distinct particle shape. Thus mixing the starting chemicals in two types of micelles, results in just one population of nanoreactors, in which particle shape. Thus mixing the starting chemicals in two types of micelles, results in just one population of nanoreactors, in which particle shape.

Fig. 4 Room temperature excitation spectra of the (a) [Eu(W5O18)2]/SiO2 (1), (b) [Tb(W5O18)2]/SiO2 (2) and (c) [Eu(W5O18)2(picOH)4]/SiO2 (6). The monitoring wavelengths were 544 nm and 611 nm for the Tb3+ and Eu3+-containing materials, respectively.

Fig. 5 Digital photographs of solid nanocomposites [Eu(W5O18)2]/SiO2 (1) (left) and [Eu(W5O18)2(picOH)4]/SiO2 (6) (right) under (a) white light, (b) 366 nm and (c) 254 nm radiation; and (d) a suspension of 1 in ethanol under 254 nm radiation. The blue shadow is due to reflection of the UV light.

The excitation spectra (Fig. 4) of the [Eu(W5O18)2]/SiO2 (1) and [Tb(W5O18)2]/SiO2 (2) compounds were monitored within the 5D0 → 7F2 and 5D4 → 7F5 transitions, respectively. The spectra display a broad band and a series of intra-4f lines ascribed to the 7F0,1 → 5D4, 7F2,6, 5D4(Eu3+) and 7F0 → 5L6, 5G2, 5H4, 5D4, 5D2, 4D2, 4D4 Tb3+ transitions. The broad band has a main component at 262 and 250 nm for the [Eu(W5O18)2]/SiO2 (1) and [Tb(W5O18)2]/SiO2 (2) nanocomposites, respectively, and a shoulder around 290 nm observed for both materials. The fact that this latter component is present in the spectra of both Eu3+- and Tb3+-based POM, suggests that it may arise from O → W ligand-to-metal charge transfer (LMCT) state. In fact, the presence of O → W LMCT in the same region was recently reported for surfactant encapsulated [EuW10O36]9− polyoxometalate. The bands at higher energies should belong to O → Eu and O → Tb LMCT states. The excitation of the [Tb(W5O18)2]/SiO2 (2) nanocomposite also shows a broad band at 410 nm, probably due to LMCT transitions ascribed to O → W/Tb transitions typical of polyoxometalates.

When using the POM-picOH organic–inorganic hybrid as starting material, Na14[Eu(W5O18)2(picOH)4]·15H2O, a POM-picOH/SiO2 core/shell nanostructured material was also obtained (Fig. 1c), with the FTIR and FT-Raman spectra showing extra bands for the organic moiety (see Fig. S1c and S2c in the ESI† for the spectra of starting POM-picOH). The effect of the organic ligand can be observed in normal digital photographs (Fig. 5) of the solid samples under UV irradiation. The [Eu(W5O18)2(picOH)4]/SiO2 (6) nanocomposite shows emission under 366 nm radiation that is not visually observed for [Eu(W5O18)2]/SiO2 (1). The nanocomposites prepared form stable colloids, both in water and in ethanol, whose emission is still observed under a UV lamp at 254 nm (Fig. 5d).

The effect of incorporating the organic ligand (picOH) in the lanthanide ion excitation path was monitored for the [Eu(W5O18)2(picOH)4]/SiO2 (6) nanocomposite. Fig. 4 also shows the excitation spectrum of 6 monitored within the 5D0 → 7F2 transition. The spectrum shows the O → Eu and O → W LMCT bands at around 260 and 290 nm, respectively, already detected for [Eu(W5O18)2]/SiO2 (1), and a band between 300 and 400 nm which arises from the picOH excited states. The temperature decrease from 300 to 14 K, favours the contribution of the picOH excited states relatively to that of the LMCT ones (see Fig. S5 in the ESI†). The incorporation of the organic counterpart contributes to enhance the Eu3+ sensitization as the low-relative intensity of the 7F0,1 → 5D4, 5D2, 4G2, 4E, 4F3/2, 4F1/2 Eu3+ intra-4f lines points out, when compared with those in [Eu(W5O18)2]/SiO2 (1), in agreement with picOH coordinated to the lanthanide center.

Fig. 6 compares the room temperature emission spectra of the [Eu(W5O18)2]/SiO2 (1) and [Tb(W5O18)2]/SiO2 (2) nanocomposites under different excitation wavelengths. For excitation wavelengths below 300 nm the emission spectra display essentially the intra-4f lines attributed to the 5D0 → 7F2,4(Eu3+) and 5D4 → 7F6,0 (Tb3+) transitions. Increasing the excitation wavelength induces the appearance of a large broad band in the 380–500 nm region which may be originated within the SiO2 host. The emission spectrum of the hybrid material,
[Eu(W₅O₁₈)₂(picOH)₄] /SiO₂ (6), also depends on the excitation wavelengths; for excitation wavelength below 280 nm the spectra show the Eu³⁺ intra-4f⁶ lines whereas for higher excitation wavelengths a broad band blue-shifted with respect to that of 1 and 2 is also detected. This band can be ascribed to the presence of the picOH ligands. ¹, ²⁶, ²⁸

Aiming to investigate the influence of the (picOH) ligand on the Eu³⁺-local coordination, the photoluminescence features of the [Eu(W₅O₁₈)₂(picOH)₄] /SiO₂ (6) and [Eu(W₅O₁₈)₂] /SiO₂ (1) were further studied. To perform this analysis we will focus in the energy of the non-degenerated 5D₀ /C₆ line for the hybrid material 6 with respect to that of 1 suggests that for the former material the Eu–O bonds are (on average) less covalent. ¹⁶–³⁸ Such an assumption is based on the fact that the energy of the ¹D₀ /C₆ transition is related to the so-called nephelauxetic effect, in which the red shift observed for d–d and f–f energy differences with respect to the free ion, is related to a decrease in the values of the Slater integrals and spin–orbit coupling parameter. ¹⁶–³⁹ The less covalent nature of the Eu–O bonds in 6 is in good agreement with the presence of picOH in the first coordination sphere of the lanthanide inducing an increase of the Eu–O distance. The similar fwhm₀₀ values points out an analogous distribution of the Eu³⁺ ions within materials (1) and (6). At 14 K the emission spectra of [Eu(W₅O₁₈)₂(picOH)₄] /SiO₂ (6) resembles that acquired at 300 K, whereas for [Eu(W₅O₁₈)₂] /SiO₂ (1) it is observed an increase in the number of Stark components. In particular, it is observed the presence of 5 Stark components for the D₀ /C₆ → F₂ transition under LMCT excitation (Fig. S6 in the ESI†), supporting the presence of a second Eu³⁺ local environment, which is thermally quenched at room temperature.

The ⁵D₀ (Eu³⁺) and ³D₄ (Tb³⁺) lifetime values of the [Eu(W₅O₁₈)₂] /SiO₂ (1), [Eu(W₅O₁₈)₂(picOH)₄] /SiO₂ (6) and [Tb(W₅O₁₈)₂] /SiO₂ (2) were measured at 300 K under direct intra-4f⁴ (393 nm) and intra-4f⁸ (377 nm) excitation, respectively, by monitoring the more intense emission line. All the curves are well reproduced by a single exponential function (not shown) yielding lifetime values of 0.736 ± 0.003, 0.319 ± 0.003 and 0.198 ± 0.002 ms for 1, 6 and 2, respectively.

The photoluminescence features of Eu³⁺/Tb³⁺ and Eu³⁺/Gd³⁺ co-doped nanoparticles were also investigated in the 14–300 K temperature range. The emission features of the [Eu(W₅O₁₈)₂Tb(W₅O₁₈)₂] /SiO₂ (4) nanocomposite (Fig. 7) are strongly dependent on the temperature. At room temperature the emission resembles that of the single lanthanide-doped [Eu(W₅O₁₈)₂] /SiO₂ (1). At 14 K the Tb³⁺ ions are optically active, so that the emission results from the overlap of the Eu³⁺ and Tb³⁺ ⁵D₀ → F₂ transitions, respectively (inset of Fig. 7), showing a series of Eu³⁺ intra-4f⁶ and Tb³⁺ intra-4f⁸ lines, respectively, and a broad band with two components at 290 nm attributed to the O → W LMCT band and a component at 330 nm not present in single lanthanide doped nanoparticles. The non-observation of the Tb³⁺ excited levels in the excitation spectra monitored within the Eu³⁺ intra-4f⁶ transitions is a clear evidence that no effective Tb³⁺-to-Eu³⁺ energy transfer occurs at 14 K (as also observed at room temperature).

The photoluminescence of the [Eu(W₅O₁₈)₂Gd(W₅O₁₈)₂] /SiO₂ (5) nanoparticles in the 14–300 K temperature range (not shown) resembles the above mentioned features of the [Eu(W₅O₁₈)₂] /SiO₂ (1) nanoparticles. Therefore, similarly to that found for the Eu³⁺/Tb³⁺ co-doped nanoparticles no effective interaction exists between Gd³⁺ and Eu³⁺ ions.

**Fig. 6** Room temperature emission spectra of (a) [Eu(W₅O₁₈)₂] /SiO₂ (1), (b) [Tb(W₅O₁₈)₂] /SiO₂ (2) and (c) [Eu(W₅O₁₈)₂(picOH)₄] /SiO₂ (6) excited within 250–300 nm (solid line) and 365–375 nm (solid line and circles).

**Fig. 7** Emission spectrum (14 K) of [Eu(W₅O₁₈)₂Tb(W₅O₁₈)₂] /SiO₂ (4) excited at 340 nm. The inset shows the excitation spectra monitored at 544 nm (solid line) and 701 nm (solid line and circles).
To further quantify the emission features of all the composite nanoparticles, the absolute emission quantum yield was measured for direct intra-4f excitation (Tb\(^{3+}\), 288 nm) and Eu\(^{3+}\), 373 nm), via the LMCT (260–290 nm) states and through the picOH excited states for the hybrid POM. For all the materials, the maximum quantum yield value was attained under UV excitation at 260 nm. For the [Eu(W\(_5\)O\(_{18}\)]\(_2\)/SiO\(_2\) (395 nm), the lanthanide ion, which is in good agreement with the presence of 0.05 was found after coordination of the picOH organic ligand to a polyoxometalate-based material with K\(_1\)Eu(Si-3318
